

DevAssist Architecture and Database Layout Guide

This document describes the secondary developer configurations and RAG indexing layout for the DevAssist documentation platform. The platform operates a local database shimming layer that enables standard semantic search without native dependencies.

Vector Database Mechanism

DevAssist utilizes a flat-file database schema to maintain high performance in restricted environments. The system scans, chunks, and writes embeddings directly to `backend/chroma_db/document_store.json`. When calling query searches, the database computes cosine similarity across all stored float array keys.

GitHub MCP Server Integrations

The action layer of DevAssist connects directly to a subprocess running FastMCP. The client routes all destructive issues and comments through a validation middleware, requiring users to click confirm on the UI modal panel before executing state modifications. To customize this flow, developers can modify the `system_prompt.txt` or `query_rewrite_prompt.txt` files directly to change the underlying rules of LLM tool selection.
